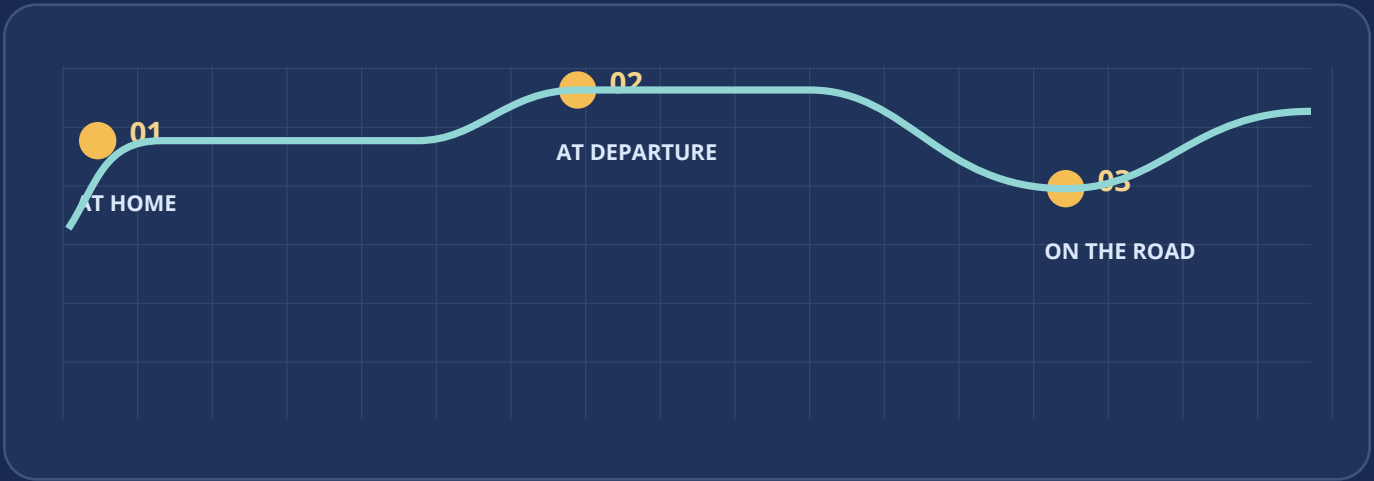
BD ELECTRICAL & SOLAR

TECHNICAL WHITE PAPER / NOVEMBER 2026

The Winter EV Playbook

Charge smarter, plan around real winter range, and understand what your battery is doing in the cold.



A practical guide for New England drivers

For daily commuters, outdoor parkers, road-trippers, and anyone sizing a home charger.

What the cold actually changes

A cold pack and a worn-out pack are not the same thing. Treat range, charging speed, and long-term wear as separate questions.

The trip costs more energy.

Cabin heat and window defrost draw energy. Every cold start has a warm-up cost, so five short errands with long stops can be less efficient than one loop of the same mileage. Cold air is denser, and slush, wind and winter tires can add rolling or aerodynamic load. Heat pumps are usually more efficient than resistance heat in suitable conditions, but the advantage depends on the car and weather. [1, 2]

The pack can temporarily deliver and accept less.

Low temperature raises cell impedance and slows internal transport. Voltage drops more under load, and the car may limit power, charging or regenerative braking until it warms up. A cold morning's range estimate is not a battery-health test. High charge can also limit regen because the pack has little room to take energy back. [1, 3, 4]

Fast charging a cold cell is a different problem.

In many lithium-ion cells the anode is graphite. During charging, lithium normally enters that graphite. If the cell is too cold or current is too high, metallic lithium can deposit on the anode instead. This is called **lithium plating**; it can cause lasting damage. The battery management system (BMS) may heat the pack and cap current to protect it. Don't try to override that protection. [3]

READ A WINTER RANGE STUDY CORRECTLY

A U.S. Department of Energy program record shows about **41% less range at 20°F** in its battery-electric test comparison against 72°F. That is a test result, not a discount to apply to every EV. Use your own vehicle, route and weather to plan. [1]

Long-term wear is a separate clock.

Calendar aging happens even while parked; cycle aging accumulates with battery use. Time at high charge can accelerate calendar aging, especially in heat, but the effect is chemistry- and cell-specific. A few extra percentage points for a cold trip are an operating choice, not a precise trade of range for years of battery life. [12]

Set a charge limit you can live with

The right daily target depends on the pack, the manufacturer's guidance and how much margin you need tomorrow.

Pack or label	What it means	Practical rule
NMC / NCA	Nickel-manganese-cobalt / nickel-cobalt-aluminum cathodes. These labels don't tell you the car's hidden buffers or daily limit.	Use the vehicle's recommended daily limit. Where permitted, pick a lower target only if it still leaves enough range. Save higher limits for trips and aim to finish close to departure when practical.
LFP	Lithium iron phosphate, also lithium-ion. Voltage is relatively flat through much of its charge range, making state of charge harder to infer from voltage alone. [5]	Some models specify occasional or regular full charges for battery estimation. Follow the model's rules. For example, one Ford manual calls for a full charge at least monthly on LFP, but a 90% everyday limit on its nickel-based pack. [6, 13]
4680	A cylindrical cell size, roughly 46 mm by 80 mm, not a cathode chemistry.	Identify the actual pack by the vehicle's charging screen or manual for your model, trim and year. Don't infer the limit from the badge or cell size.

Use a margin, not a magic percentage.

When the manual permits a choice, estimate the percentage points your hardest routine winter day uses. Add enough reserve for detours or a missed charge. Example: a day that uses 28 points plus a 20-point reserve needs at least 48% at departure; a 60% or 70% target may be workable on a model that permits it. The extra ten points buy buffer. There's no reliable universal percentage for the long-term wear difference.

BEFORE A TRIP, STORM OR LONG PARK

Use more charge when the drive, forecast or sparse chargers justify it. Return to your normal limit afterward. For multiweek parking, use the specific storage procedure in your manual rather than copying another vehicle's percentage or plug-in advice. [6]

FIGURE A / THERMAL BASICS

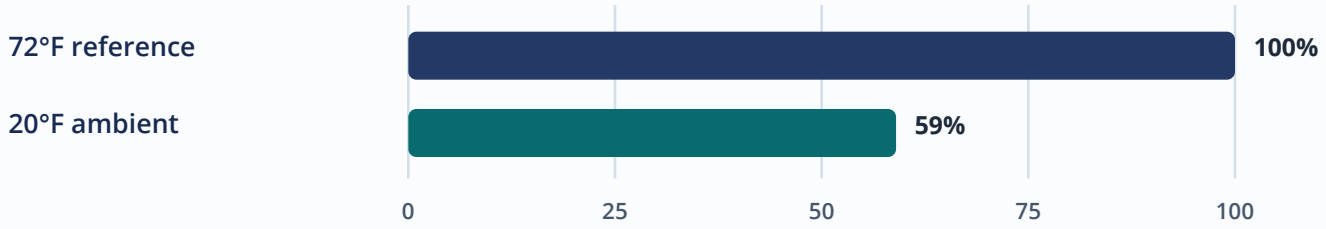
Winter range, in pictures

A measured range comparison and a schematic of what happens on a cold start.

A1 / CONTROLLED TEST

How much range remained at 20°F?

Index: 72°F ambient = 100%. The cabin was maintained at 72°F.



Source: DOE program record, Figure 1 (Argonne weighted city/highway dynamometer comparison). Different EVs, HVAC settings and roads can show very different results. [1]

A2 / CONCEPTUAL

Three things a cold driver can notice

These are mechanisms, not an energy split or a prediction for a particular pack.

01

More cabin load

Glass, cabin air and surfaces need heat. Repeated cold starts can repeat that cost.

02

Less usable power

Cold cells have higher impedance. The car may temporarily limit power and regenerative braking.

03

Lower charge acceptance

The BMS may warm the pack or reduce current to limit plating risk. [1, 3, 4]

DON'T DIAGNOSE AGING FROM THE DASH

If range returns when the pack and weather warm up, that cold-morning decrease was not, by itself, proof of capacity loss.

Size for the coldest ordinary day

Charging power is measured in kW. Your drive and your electric bill are measured in kWh. You need both to size the overnight window.

Example supply	Power at wall	7 h gross energy	Hours for 17.5 kWh*
Level 1 · 120 V / 12 A	1.44 kW	10.1 kWh	13.5 hours
Level 2 · 240 V / 16 A	3.84 kW	26.9 kWh	5.1 hours
Level 2 · 240 V / 24 A	5.76 kW	40.3 kWh	3.4 hours
Level 2 · 240 V / 32 A	7.68 kW	53.8 kWh	2.5 hours
Level 2 · 240 V / 48 A	11.52 kW	80.6 kWh	1.7 hours

*Illustrative: 50 miles × 0.35 kWh/mi = 17.5 kWh on the vehicle side; assume 90% wall-to-pack efficiency for arithmetic and no separate preheat allowance. Actual conversion and conditioning losses vary. Table amps are charging current, not breaker ratings. Vehicle, station and load management may cap draw. [7]

Work backward from your available hours.

Average wall power needed ≈ (driving kWh ÷ measured charging efficiency + separate plug-in heat allowance) ÷ available hours. With 17.5 kWh for driving, 90% efficiency, 2 kWh of separately measured warm-up and a 7-hour window, the example needs about 3.1 kW average from the wall. Don’t add warm-up again if it is already in your measured numbers. Try a cold week before assuming the minimum is enough.

BUY THE CURRENT YOU NEED, NOT THE BIGGEST NUMBER

A properly installed 16 A or 24 A Level 2 setup can cover many drivers. If a 120 V setup loses ground every morning, widen the charging window or plan a Level 2 top-up. Use listed equipment with a properly rated dedicated circuit, follow manufacturer instructions, and have an electrician check service capacity and outdoor suitability. Skip extension cords and improvised adapters. [7]

Give one device the schedule

The car can't preheat on wall power if a second timer has turned the charger off. Decide what matters most: readiness, electricity price, or both.

Your setup	First schedule to try	What to verify
Flat rate	If the vehicle offers a finish-by setting, start with a finish time near departure. Set scheduled departure preconditioning separately if your vehicle distinguishes the two. [8, 9]	Actual finish, departure charge and wall kWh. Charging late can help on some cars, but it doesn't guarantee a warm pack or full regen.
Off-peak ends near departure	Keep charge inside your low-rate window when possible. Use the vehicle or EVSE as the main timer; let the other be available.	Test once at low charge. Check whether the vehicle can start early or spill past your window, and what happens at midnight or after a missed plug-in.
Off-peak ends before departure	Finish bulk charging off-peak; compare preheating just before you leave with warming while the cheap window is still open.	Measure total cost *and* departure charge. A short peak-rate warm-up may be worth the extra range or clear glass; don't sacrifice visibility to save cents.
120 V or shared power	Start earlier or keep the car connected longer. Avoid counting on a short cheap-rate window after heavier days.	Preheat can exceed the available wall power. Look for a lower departure charge or a slow recovery trend, especially on consecutive cold days.

THE MISSED-NIGHT CHECK

Run the schedule once on a day when you can afford a miss. Plug in, verify the car sees the charger, look at the app after the start time, and check actual wall kWh the next morning. If it misses, disable one schedule before changing amperage. Cabin remote start and traction-battery preconditioning are not always the same feature. [8, 9, 10]

FIGURE B / HOME CHARGING

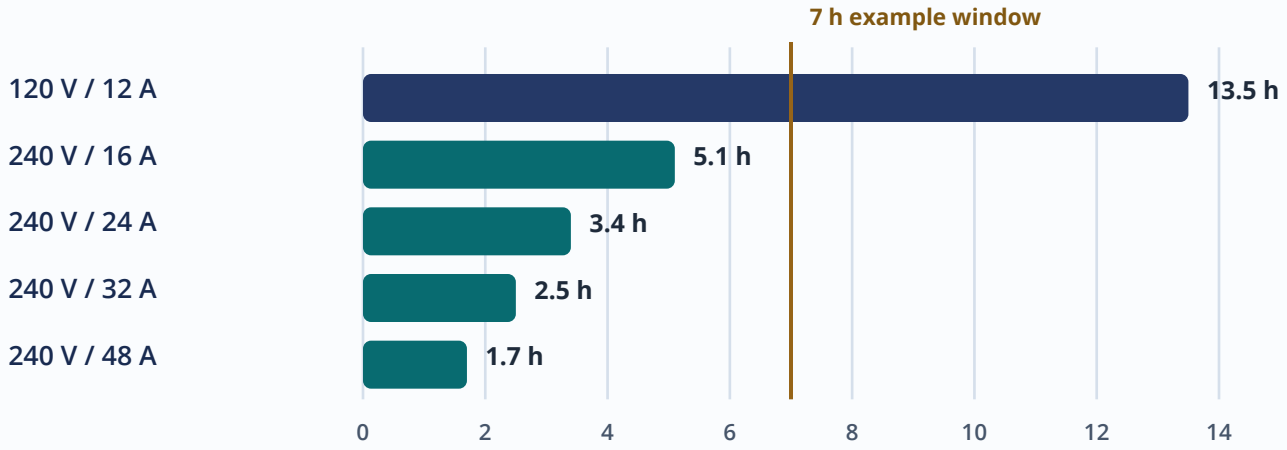
What fits overnight?

Size the circuit around an energy target, then check that your charging and preheat schedules actually work together.

B1 / WORKED EXAMPLE

One 17.5 kWh refill, five power levels

Hours at the wall, assuming 90% charging efficiency and no separate preheat load.

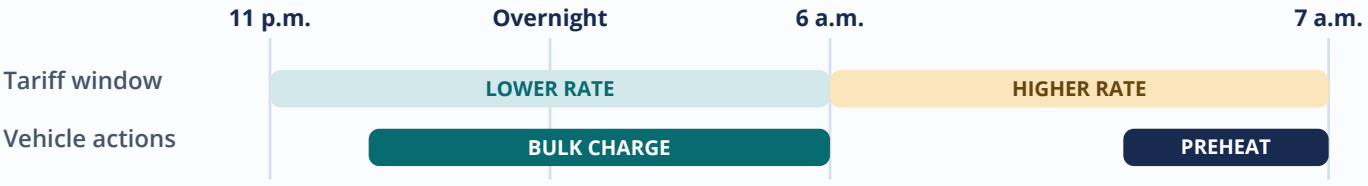


Worked example from the home-charging table. Actual draw can be lower, and conditioning can lengthen the session. Current shown is charging current, not breaker size. [7]

B2 / EXAMPLE SEQUENCE

Let the car preheat while power is available

Example: low-rate window ends at 6 a.m.; leave at 7 a.m. Schematic, not to scale; charging and heating durations vary.



If a charger-side timer cuts the supply at 6 a.m., the car may preheat from its battery. If your car supports it, let the vehicle handle the schedule and check the actual wall meter the next day. [8, 9]

Charge for the next leg, not to 80%

The station's label is a ceiling, not your session average. A cold pack, a high starting charge or a constrained station can all set a lower limit.

Navigate to the charger with the car.

On supported models, select the actual DC site in the vehicle's built-in navigation early enough for conditioning to run. A phone map may not trigger pack heating. Some cars also have a manual mode, and some suspend heating at low charge. Look for the vehicle's conditioning indicator. If an early stop is flexible, charging after a drive can be faster than charging immediately after an overnight cold soak. [8, 10]

If the rate is low, identify the bottleneck.

Check battery percentage, conditioning status and whether the rate is climbing as the pack warms. If the car is warm and at a low-to-mid charge, check the network app or stall screen for reduced power or sharing; use another compatible stall if the operator indicates a fault or derate. A higher-rated stall cannot overcome your vehicle's limit. [2, 7]

Estimate the stop in minutes, not peak kW.

For a 75 kWh usable pack, 15% to 60% adds about 34 kWh. At an average 80 kW *into the pack* that is about 25 minutes, versus about 45 minutes at 45 kW. This is arithmetic, not a modeled charging curve. Add time for approach, queues, connection and payment. Higher charge usually tapers; leave after you've bought the next leg and reserve, unless sparse sites or weather justify staying. [2, 7]

DO THE BACKUP MATH BEFORE RELYING ON THE FIRST STALL

Confirm connector and any approved adapter, operating status, access hours, and a backup you can still reach if the first site is down. In a storm, use stations with multiple working stalls when practical. Don't plan to arrive near empty just to chase a faster charge. [7, 11]

Budget the worst leg, not the whole trip

Use the car's live arrival estimate plus a plan you can check with a calculator. Keep traction and visibility ahead of efficiency.

Translate the forecast into a departure target.

Required departure % ≈ 100 × (leg miles × cold kWh/mi + extra contingency kWh) ÷ usable pack kWh + arrival reserve %. Example: 100 miles × 0.40 kWh/mi = 40 kWh. With 5 kWh for a reachable backup detour, 75 kWh usable and a 15% reserve, target **75%**. Set the reserve based on charger spacing, weather and alternatives; 15% is illustrative, not a rule. If the target exceeds your practical charge or the route deteriorates, add a stop, reroute or postpone.

Set a decision point before the last good exit.

Use recent winter consumption on a similar highway leg, not an annual average. Check predicted arrival after the first 15–25 miles and again before the last reliable alternate. If it's slipping toward your reserve, adjust speed only when safe and legal, or stop sooner. If your backup is 20 miles beyond the first site, explicitly budget those 20 miles at your cold-weather consumption.

Keep the glass clear

Preheat while plugged in if available, then use seat and wheel heat for comfort where safe. Keep defrost on whenever needed. Brush snow from the roof, lamps, sensors and charge door; use winter-rated washer fluid. [2, 11]

Keep traction ahead of regen

Check cold tire pressure against the driver-door placard. Use adequate winter tires for your conditions, increase following distance, and be smooth with pedals and steering. Follow your manual for snow modes and regenerative braking on slick roads. [4, 11]

COLD HARDWARE: PROTECT THE CONNECTOR

Keep the connector holstered and cable out of the plow path. Use the manufacturer's approved thawing procedure for a frozen port or latch; don't force it. A spare compatible charging option and normal winter roadside kit matter more than another dashboard setting. [4, 11]

FIGURE C / ROAD-TRIP MATH

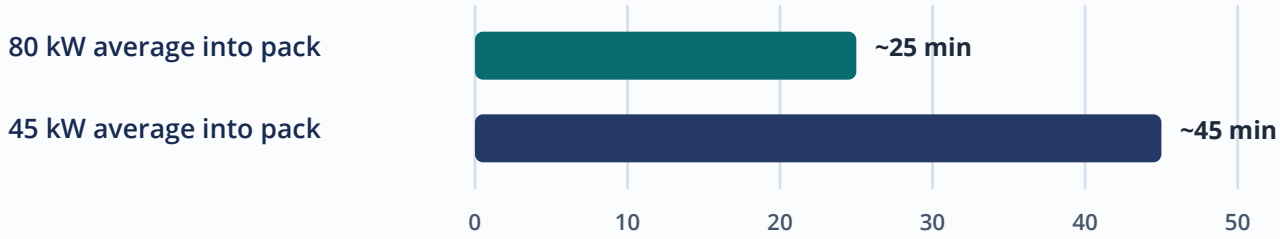
Minutes and miles

Use average charge power for the stop and a separate energy budget for the next leg.

C1 / SAME ENERGY, DIFFERENT STOP

About 34 kWh can take 25 or 45 minutes

Illustrative 75 kWh usable pack, from 15% to 60%; charging time only.



These are worked examples, not a station rating or a charging-curve prediction. Add queue, access, plug-in and payment time. [2, 7]

C2 / ROUTE BUDGET

A 75% departure target, broken down

Example: 100-mile leg, 0.40 kWh/mile, 75 kWh usable pack and a 15% arrival reserve.

40 kWh driving + 5 kWh contingency + 11.25 kWh arrival reserve = 56.25 kWh, or 75% of the pack. The unfilled 25% is not needed for this example. Set your actual reserve around conditions and available backups.

CHECK BEFORE THE LAST GOOD EXIT

If predicted arrival trends down toward the reserve, verify that the fallback still works and stop sooner when needed.

Two meters. Two real answers.

Your dashboard tells you how far the car can go. Your charger meter tells you what the routine costs. Neither can replace the other.

Run a small A/B test on your own driveway.

On two comparable pairs of cold mornings, alternate **A: early off-peak charge + plugged-in departure heat** and **B: latest tariff-compliant finish + the same departure heat**. Keep route, cabin setting, starting charge band and parking location similar. Use the charger's metered session energy plus any separate warm-up session, not a whole-home meter unless you can isolate the EV.

Record each run	Why it matters
Overnight low, wind/slush, miles and route	Compare like-for-like; don't infer savings from one warmer day.
Plug-in, departure and end-of-drive charge %	Make sure both routines start and end with comparable battery energy.
Total wall kWh, split by rate period	Compute dollars per mile using the rates you actually pay.
Driving kWh/mi and first few miles' regen / comfort	Separate on-road range benefit from energy moved to your electric meter.

Judge both outcomes.

Lower driving kWh alone may mean you moved heating to the wall. Compare runs with similar starting and ending charge, or meter through the next refill to the same target and control for that refill's conditions. At illustrative rates of 15¢ off-peak and 35¢ peak per kWh, 20 overnight kWh cost $3.00; a separate 2 kWh peak-rate preheat adds $0.70.

TWO EXTRAS WORTH TESTING

Cluster your errands: reset the trip meter and compare one loop with independent cold starts.
Audit parked draw: log parked charge across two similar nights; check scheduled climate, recording and accessory settings before blaming the battery, and keep any security features you rely on.
